## ABSTRACT

Recent technical advances in electrophysiological recording and functional imaging from the brain of living animals have promoted our understandings of the brain function, but these *in vivo* experiments are still technically demanding and often suffer from spontaneous pulsation, *i.e.*, brain movements caused by respiration and heartbeat. Here we report that thoracotomy suppresses the motion artifact to a practically negligible level. This simple method will be useful in a wide variety of *in vivo* experiments, such as patch-clamp physiology, and optical imaging of neurons, glial cell, and blood vessels.

*In vivo* recordings from the brain are often perturbed by spontaneous beating of the brain. This brain motion is thought to arise from mechanical instability associated with respiratory and heartbeat pulsation (Dichter, 1973). Consistent with this notion, the intracranial pressure is known to fluctuate in cardiac and respiratory rhythms (Avezaat and van Eijndhoven, 1986).

In order to stabilize *in vivo* recording, researchers have empirically devised a number of strategies. The methods include: making use of mechanical ventilation with small tidal volumes at rapid rates (Kandel et al., 1961; Todd et al., 1981); lifting up the animal's head and suspending the animal's trunk in a hammock (Britt and Starr, 1976; Dichter, 1973); performing bilateral pneumothoraces and ventilating the animals (Britt and Starr, 1976; Dichter, 1973; Kandel et al., 1961); placing liquid agarose on the craniotomized hole to fix the brain into a closed system (Britt and Starr, 1976; Dichter, 1973); draining the cerebrospinal fluid (Britt and Rossi, 1982); acquiring images triggered on cardiac and respiratory oscillation phases (Megens et al., 2010); and developing an online actuator to compensate the position of a recording electrode relative to the brain (Fee, 2000). In addition, respiration noise can

be removed by temporarily stopping an artificial respiration apparatus (Taniguchi et al., 1992), although the cardiac noise must be removed offline by subtracting the background obtained from trials without stimuli (Fukunishi and Murai, 1995; Taniguchi et al., 1992) and by using independent component analysis (Inagaki et al., 2003; Maeda et al., 2001), the Lucas–Kanade algorithm (Greenberg and Kerr, 2009), and a hidden Markov model (Chen et al., 2010; Dombeck et al., 2007).

All these methods have been proven valid to some extent, but they may be impractical in terms of their low versatility and procedural complication. In the present study, we demonstrate that the brain pulsation is virtually eliminated by performing thoracotomy in anesthetized mice.

All experiments were performed with the approval of the animal experiment ethics committee at the University of Tokyo (approval number: 19-35) and according to the University of Tokyo guidelines for the care and use of laboratory animals. Male postnatal day 20–27 ICR mice ( $29.4 \pm 5.0$  g, Japan SLC, Shizuoka, Japan) or mice expressing membrane-targeted green fluorescent protein (GFP) (line 21, thy1-GFP transgenic C57B6 mice), a gift from Dr. V. de Paola and Dr. P. Caroni (De Paola et al., 2003), were given free access to food and water and maintained under controlled temperature and light schedules. Mice were anesthetized by intraperitoneal urethane (1.5 g/kg) and given tracheal cannulation. The exposed skull was glued to a metal plate, through which the mice was fixed to a stereotaxic frame. The 1 mm × 1-mm skull was craniotomized

at 3.5 mm posterior, 1.5 mm lateral to the bregma, which corresponded to the primary visual cortex. After the surgical removal of the dura, the exposed cortex was mounted with 1.5% agar at a thickness of 0.5 mm and covered by a 170- $\mu\text{m}$ -thick glass coverslip (Kuga et al., 2011; Takahara et al., 2011). The animals were ventilated using a volume cycled ventilator (120 breaths/min, Shinano, SN-480-type7, Tokyo, Japan). The tidal volume ranged from 12 to 20 ml/kg, but it was initially set to be 16 ml/kg, unless otherwise specified. Rectal temperature was kept at 37 °C by placing the mouse on a heated plate (Thermo plate MATS-505SF; TOKAI HIT, Shizuoka, Japan). Heart rate and blood pressure were monitored through non-invasive recordings using a BP-98AL tail-cuff device (Softron, Tokyo, Japan) (Minamisawa et al., 2011).

Fluorescein isothiocyanate (FITC)-labeled dextran (70 kDa, 0.3%, 600 ml/kg) was intravenously injected into the retro-orbital venous plexus, and the brain blood flow was angiographically imaged at 50 frames per s with a Nipkow-disk confocal unit (CSU-X1; Yokogawa Electric, Tokyo, Japan), a cooled CCD camera (iXon DU887; Andor Technology, Belfast, UK), an upright microscope (Axio Examiner D1, Carl Zeiss, Oberkochen, Germany) with a water-immersion objective (40 $\times$ , 0.8 numerical aperture, Carl Zeiss), and image acquisition software (SOLIS; Andor Technology). Fluorophores were excited at 488 nm with an argon-krypton laser (10–15 mW, 641-YB-A01; Melles Griot, Carlsbad, CA, USA) and visualized using a 507-nm long-pass emission filter. After obtaining the “baseline” level of pulsation in a few microscopic fields, the mice were thoracotomized, and the same blood vessels were imaged. Region of interests (ROIs) were placed across blood vessel walls, and the fluorescence change  $\Delta F/F$  was calculated as  $(F_i - F_0)/F_0$ , where  $F_i$  is the fluorescence intensity at time; and  $F_0$  is the baseline value averaged across the 20-s period before and after the focused time. Data were analyzed using Image J and Matlab.

Using medical scissors, an incision was made between the costae and the sternum on the right chest from the clavicle to the diaphragm along the body axis 2–3 mm aside from the median line with a caution to avoid injury of the lungs and heart. This surgical procedure did not cause significant hemorrhage, and no specific treatment was required to the incised part.

Data are reported as the means  $\pm$  standard deviations (SD).

To investigate the effect of thoracotomy on the vital conditions of the animals, we monitored the heartbeat and the blood pressure using a tail-cuff measure device. This apparatus uses an infrared sensor to measure the pulsing of the caudal artery, and the measured blood pressure may not reflect the true values, although the heart rate can be accurately measured. We thus compared the relative values of the mean blood pressure before and after thoracotomy in an arbitrary unit. The mean blood pressures under control and thoracotomized states were  $47.3 \pm 7.3$  and  $36.6 \pm 2.0$ , respectively, and the heart rates were  $509.4 \pm 154.6 \text{ min}^{-1}$  and  $553.3 \pm 138.5 \text{ min}^{-1}$ , respectively (mean  $\pm$  SD = 4 mice). The blood

pressure and heart rate tended to be decreased and increased, respectively, after thoracotomy, but these changes were not statistically significant ( $P > 0.05$  paired *t*-test). Thereafter, the animals maintained the blood pressure and heart rates within a 30% change in fluctuations for more than 6 h. Because thoracotomy increases the intrathoracic pressure from the negative value relative to the atmospheric pressure to nearly zero, optimizing the tidal volume may be critical in maintaining the vital conditions of the animals. To examine how the tidal volume influences the heartbeat rate and the blood pressure, we adjusted the tidal volume to 12, 16, and 20 ml/kg. The blood pressures were  $38.3 \pm 3.8$  for 12 ml/kg,  $36.5 \pm 2.0$  for 16 ml/kg, and  $33.0 \pm 0.9$  for 20 ml/kg, whereas the heart rates were  $548.2 \pm 127.8 \text{ min}^{-1}$  for 12 ml/kg,  $553.3 \pm 138.5 \text{ min}^{-1}$  for 16 ml/kg, and  $561.0 \pm 132.4 \text{ min}^{-1}$  for 20 ml/kg. Thus, the tidal volume was unlikely to affect these cardiovascular parameters, and thus, we used 16 ml/kg in the following experiments.

The hydrophilic fluorophore FITC-dextran was intravenously injected into anesthetized mice, and the brain vessel was visualized using a Nipkow-disk confocal microscope and a fast-scanning CCD camera (Fig. 1A). We observed pulse-like movement of vessels in all mice tested. The amplitude of the fluctuations ranged typically from 10 to 30  $\mu\text{m}$ , which corresponded nearly to the diameters of arterioles and capillaries. The degree of the fluctuation varied from animal to animal, but not from vessel to vessel within each animal. This indicates that the movement of vessels arose from pulsation of the cortical surface around the craniotomized region or the entire brain. Consistent with this, we found that neurites and vessels moved spatially in parallel to each other in the brain in a thy1-GFP mouse, which expressed GFP sparsely in a subset of neurons (De Paola et al., 2003) (Supplemental Movie 1). Therefore, the movement of vessels serves as a good index of the pulsation of other brain components, including neurons and glial cells.

To quantify the extent of pulsation, we measured the fluorescence intensity  $F$  in ROIs at the borders between vessel walls and brain parenchyma and calculated  $\Delta F/F$  as fluorescence changes from the baseline (Fig. 1B). The  $\Delta F/F$  values showed periodic oscillations (Fig. 1B inset). The rhythmicity was analyzed with the fast Fourier transform (FFT) and unfolded into the power spectrum. The spectrum exhibited two prominent peaks around 2 Hz and 8 Hz (Fig. 1C). These peaks were thought to correspond to respiration and heartbeat, respectively; note that the ventilator was set at 120 breaths/min ( $\approx 2$  Hz) and the heart rate, as measured above, was about 500 beats/min ( $\approx 8$  Hz).

We evaluated the strength of the oscillations by calculating the power integral of the peak, *i.e.*, the area under a curve (Fig. 1D). We repeated this analysis for 5 mice and found that the power integral of the heartbeat was  $3.2 \pm 1.9$ -fold larger in that of respiration ( $T = 0.00$ ,  $P < 0.01$  Wilcoxon signed-ranked test). Thus, the cardiac

movement contributes significantly more to brain pulsation than respiration.

After recording under control conditions, the right chest of the mice was incised between the costae and the sternum (Fig. 2), and the same blood vessels were re-imaged (Fig. 3A). After thoracotomy, the amplitude of the vessel movement appeared to be less than  $1\ \mu\text{m}$ . We compared the power spectrum of the fluctuations in  $\Delta F/F$  before and after thoracotomy (Fig. 3B) and found a dramatic reduction in two FFT peaks (Fig. 3C). Data were collected from 78 ROIs from 5 mice and plotted in the 'before-versus-after' space (Fig. 3D). Respiration-relevant and heartbeat-relevant power integrals were both attenuated in thoracotomized mice (respiration:  $t_{77}=9.91$ ,  $P=2.2 \times 10^{-15}$ ; heartbeat:  $t_{77}=6.46$ ,  $P=8.4 \times 10^{-9}$ ; paired  $t$ -test). On average, thoracotomy decreased the FFT power by  $82.3 \pm 11.7\%$  in respiration and  $87.2 \pm 7.1\%$  in heartbeat. Heartbeat-induced pulsation was more strongly suppressed ( $t_{77}=3.02$ ,  $P=3.4 \times 10^{-3}$ ; paired  $t$ -test).

We have demonstrated that thoracotomy efficiently suppressed the brain pulsation *in vivo*. Nipkow-disk confocal microscopy enables high-speed scanning from a wide microscopic field, allowing us precise evaluations of the degrees of fluctuations in  $\Delta F/F$ . To our knowledge, this work is the first to quantify the brain pulsation in the order of micrometers and precisely separate the respiratory and cardiac contributions. This novel FFT-based quantification will be useful in qualifying individual preparations.

Moreover, we propose surgical thoracotomy as a new strategy to reduce the contribution of respiration and heartbeat. An important advantage of this surgery is its technical simplicity, which does not require specialized equipment, complex devices, or biological manipulation. The procedure is not laborious, time-consuming, or cost-consuming, as compared to methods previously reported to overcome the pulsation. Although we evaluated the effect of thoracotomy by monitoring vessels only, thoracotomy is also thought to suppress the motion artifact of other brain components, such as neurons and glial cells, because the pulsation is a rather global phenomenon in the cerebral cortex around the craniotomized surface or even the entire brain (see Supplemental Movie 1).

Although there could be several reasons that explain the effect of thoracotomy, we believe that it is attributable mainly to an

**Fig. 3.** Thoracotomy-induced suppression of pulsation. (A) Representative image of neocortical blood vessels. (B) Fluctuations in the fluorescence intensity before (control, top) and after thoracotomy (thoracotomized, bottom) in the ROI of (A). (C) FFT power spectra before (left) and after thoracotomy (right). (D) Comparison of the power integral of respiration (left) and heartbeat (right) before (abscissa) and after thoracotomy (ordinate) in 78 ROIs from 5 mice,  $t_{77}=9.91$ ,  $p=2.2 \times 10^{-15}$  (respiration);  $t_{77}=6.46$ ,  $p=8.4 \times 10^{-9}$  (heartbeat); paired  $t$ -test.

increase in the intrathoracic pressure. Under intact conditions, the lung and the heart are tightly packed in the pleural cavity through the negative intrathoracic pressure relative to the barometric pressure. Therefore, their intrinsic movements are transmitted to the cephalic part, including the brain, via the spine, the respiratory tract, neck muscles, etc. Thoracotomy increases the intrathoracic pressure to the atmospheric pressure and releases the tight packing of intrathoracic tissues, so that the lung and the heart are virtually physically (not physiologically) isolated from the trunk of the body, and their movements become rather independent of the brain. This physical relaxation may contribute to thoracotomy-induced suppression of the brain pulsation.

In awake behaving animals, the brain motion results not only from respiratory and cardiac pulsations but also from the motor activity associated with extension and contraction of the torso (Fee, 2000). This movement may not cause large cranial motion, but it may bring about the brain motion mechanically through the movement of spinal cord and the changes in intracranial and blood pressure. Our method is thus unlikely to be applicable for reducing the brain movement caused by spontaneous motion of animals during behavior under complete analgesia. Therefore, thoracotomy is the first choice to suppress pulsation in head-restricted anesthetized animals.
